 {sgupta, jhoffman, malik}@eecs.berkeley.edu

Abstract

In this work we propose a technique that transfers supervision between images from different modalities. We use learned representations from a large labeled modality as a supervisory signal for training representations for a new unlabeled paired modality. Our method enables learning of rich representations for unlabeled modalities and can be used as a pre-training procedure for new modalities with limited labeled data. We show experimental results where we transfer supervision from labeled RGB images to unlabeled depth and optical flow images and demonstrate large improvements for both these cross modal supervision transfers. Code, data and pretrained models are available at <https://github.com/s-gupta/fast-rcnn/tree/distillation>.

1. Introduction

Current paradigms for recognition in computer vision involve learning a generic feature representation on a large dataset of labeled images, and then specializing or finetuning the learned generic feature representation for the specific task at hand. Successful examples of this paradigm include almost all state-of-the-art systems: object detection [13], semantic segmentation [36], object segmentation [19], and pose estimation [49], which start from generic features that are learned on the ImageNet dataset [6] using over a million labeled images and specialize them for each of the different tasks. Several different architectures for learning these generic feature representations have been proposed over the years [31, 44, 3], but all of these rely on the availability of a large dataset of labeled images to learn feature representations.

The question we ask in this work is, what is the analogue of this paradigm for images from modalities which do not have such large amounts of labeled data? There are a large number of image modalities beyond RGB images which are dominant in computer vision, for example depth images coming from a Microsoft Kinect, infra-red images from thermal sensors, aerial images from satellites and drones,

Figure 1: Architecture for supervision transfer: We train a CNN model for a new image modality (like depth images), by teaching the network to reproduce the mid-level semantic representations learned from a well labeled image modality (such as RGB images) for modalities for which there are paired images.

LIDAR point clouds from laser scanners, or even images of intermediate representations output from current vision systems e.g. optical flow and stereo images. The number of labeled images from such modalities are at least a few orders of magnitude smaller than the RGB image datasets used for learning features, which raises the question: do we need similar large scale annotation efforts to learn generic features for images from each such different modality?

We answer this question in this paper and propose a technique to transfer learned representations from one modality to another. Our technique uses ‘paired’ images from the two modalities and utilizes the mid-level representations from the labeled modality to supervise learning representations on the paired un-labeled modality. We call our scheme ***supervision transfer*** and show that our learned representations perform well on standard tasks like object detection. We also show that our technique leads to learning useful feature hierarchies in the unlabeled modality, which can be improved further with finetuning, and are still complementary to representations in the source modality.

As a motivating example, consider the case of depth images. While the largest labeled RGB dataset, ImageNet [6] consists of over a million labeled images, the size of most existing labeled depth datasets is of the order of a few thousands [42, 46, 26]. At the same time there are a large number of unlabeled RGB and depth image pairs. Our technique leverages this large set of unlabeled paired images to trans-

fer the ImageNet supervision on RGB images to depth images. Our technique is illustrated in Figure 1. We use a convolutional neural network that has been trained on labeled images in the ImageNet dataset [6], and use the mid-level representation learned by these CNNs as a supervisory signal to train a CNN on depth images. Our technique for transferring supervision results in improvements in performance for the end task of object detection on the NYUD2 dataset, where we improve the state-of-the-art from 34.2% to 41.7% when using just the depth image and from 46.2% to 49.1% when using both RGB and depth images together. We report similar improvements for the task of simultaneous detection and segmentation [19] and also show how supervision transfer can be used for a zero-shot transfer of object detectors trained on RGB images to detectors that can run on depth images.

Though we show detailed experimental results for supervision transfer from RGB to depth images, our technique is equally applicable to images from other paired modalities. To demonstrate this, we show additional transfer results from RGB images to optical flow images where we improve mean average precision for action detection on the JHMDB dataset [27] from 31.7% to 35.7% when using just the optical flow image and no supervised pre-training.

Our technique is reminiscent of the distillation idea from Hinton *et al.* [22] (and its recent FitNets extension [39]). Hinton *et al.* [22] extended the model compression idea from Bucilua *et al.* [2] to what they call ‘distillation’ and showed how large models trained on large labeled datasets can be compressed by using the soft outputs from the large model as targets for a much smaller model operating on the same modality. Our work here is a generalization of this idea, and a) allows for transfer of supervision at arbitrary semantic levels, and b) additionally enables transfer of supervision between different modalities using paired images. More importantly, our work here allows us to extend the success of recent deep CNN architectures to new imaging modalities without having to collect large scale labeled datasets necessary for training deep CNNs.

2. Related Work

There has been a large body of work on transferring knowledge between different visual domains, belonging to the *same* modality. Initial work [32, 15, 1, 8, 24] studied the problem in context of shallow image representations. While [32, 15] sought to learn transformations between well labeled source and sparsely labeled target domains, Aytar *et al.* [1] use the source models as a parameter regularizer for target models, [8, 24] combine these two approaches into a single joint optimization problem. Chopra *et al.* [4] introduced one of the first deep architectures for visual adaptation by replicating feature extraction for each domain and producing intermediate interpolated domains, while Ghifary *et al.* [11] showed a single layer neural net could be used to learn the feature transformation between simple domain shifts.

More recently, with the introduction of supervised CNN models by Krizhevsky *et al.* [31], the community has been moving towards a generic set of features which can be specialized to specific tasks and domains at hand [7, 13, 12, 40, 23] and traditional visual adaptation techniques can be used in conjunction with such features [25]. More recently, unsupervised domain adaptation techniques have been introduced which learn to adapt deep representations so as to minimize the discrepancy between the source and target distributions [50, 10, 37].

All these lines of work study and solve the problem of domain adaptation within the same modality. In contrast, our work here tackles the problem of domain adaptation across *different* modalities. Most methods for intra-modality domain adaptation described above start from an initial set of features on the target domain, and *a priori* it is unclear how this can be done when moving across modalities, limiting the applicability of aforementioned approaches to our problem. This cross-model transfer problem has received much less attention. Notable among those include [5, 38, 48, 45, 9]. While [5, 48] hallucinate modalities during training time, [38, 45, 9] focus on the problem of jointly embedding or learning representations from multiple modalities into a shared feature space to improve learning [38] or enabling zero-shot learning[45, 9]. Our work here instead transfers high quality representations learned from a large set of labeled images of one modality to completely unlabeled images from a new modality, thus leading to a generic feature representations on the new modalities which we show are useful for a variety of tasks.

3. Supervision Transfer

Let us assume we have a modality \mathcal{M}_d with unlabeled data, D_d for which we would like to train a rich representation. We will do so by transferring information from a separate modality, \mathcal{M}_s , which has a large labeled set of images, \mathcal{D}_s , and a corresponding K layered rich representation. We assume this rich representation is layered although our proposed method will work equally well for non-layered representations. We use convolutional neural networks as our layered rich representation.

We denote this image representation as $\Phi = \{\phi_{\mathcal{M}_s, D_s}^i, i \in [1 \dots K]\}$. $\phi_{\mathcal{M}_s, D_s}^i$ is the i^{th} layer representation for modality \mathcal{M}_s which has been trained on labeled images from dataset D_s , and it maps an input image from modality \mathcal{M}_s to a feature vector in \mathbb{R}^{n_i} .

$$\phi_{\mathcal{M}_s, D_s}^i : \mathcal{M}_s \mapsto \mathbb{R}^{n_i} \quad (1)$$

Feature vectors from consecutive layers in such layered representations are related to one another by simple operations like non-linearities, convolutions, pooling, normalization

tions and dot products (for example layer 2 features may be related to layer 1 features using a simple non-linearity like max with 0: $\phi_{\mathcal{M}_s, D_s}^2(x) = \max(0, \phi_{\mathcal{M}_s, D_s}^1(x))$). Some of these operations like convolutions and dot products have free parameters. We denote such parameters associated with operation at layer i by w_s^i . The structure of such architectures (the sequence of operations, and the size of representations at each layer, *etc.*) is hand designed or validated using performance on an end task. Such validation can be done on a small set of annotated images. Estimating the model parameters w_s^i is much more difficult. The number of these parameters for most reasonable image models can easily go up to a few millions. Heretofore, state-of-the-art models require discriminative learning of these parameters using a large labeled training set.

Now suppose we want to learn a rich representation for images from modality \mathcal{M}_d , for which we do not have access to a large dataset of labeled images. We assume we have already hand designed an appropriate architecture $\Psi = \{\psi_{\mathcal{M}_d}^i \forall i \in [1 \dots L]\}$. The task then is to effectively learn the parameters associated with various operations in the architecture, without having access to a large set of annotated images for modality \mathcal{M}_d . As before, we denote these parameters to be learned by $W_d^{[1 \dots L]} = \{w_d^i \forall i \in [1 \dots L]\}$

In addition to D_s , let us assume that we have access to a large dataset of *un-annotated paired* images from modalities \mathcal{M}_s and \mathcal{M}_d . We denote this dataset by $U_{s,d}$. By paired images we mean a set of images of the same scene in two different modalities. Our proposed scheme for training rich representations for images of modality \mathcal{M}_d is to learn the representation Ψ such that the image representation $\psi_{\mathcal{D}}^L(I_d)$ for image I_d matches the image representation $\phi_{\mathcal{M}_s, D_s}^{i^*}(I_s)$ for its image pair I_s in modality \mathcal{M}_s for some chosen and fixed layer $i^* \in [1 \dots K]$. We measure the similarity between the representations using an appropriate loss function f (for example, euclidean loss). Note that the representations $\psi_{\mathcal{M}_s}^{i^*}$ and $\phi_{\mathcal{M}_d}^L$ may not have the same dimensions. In such cases we embed features $\psi_{\mathcal{M}_d}^L$ into a space with the same dimension as $\phi_{\mathcal{M}_s}^{i^*}$ using an appropriate simple transformation function t (for example a linear or affine function).

$$\min_{W_d^{[1 \dots L]}} \sum_{(I_s, I_d) \in U_{s,d}} f\left(t\left(\psi_{\mathcal{M}_d}^L(I_d)\right), \phi_{\mathcal{M}_s, D_s}^{i^*}(I_s)\right) \quad (2)$$

We call this process *supervision transfer* from layer i^* in Φ of modality \mathcal{M}_s to layer L in Ψ of modality \mathcal{M}_d .

The recent distillation method from Hinton *et al.* [22] is a specific instantiation of this general method, where a) they focus on the specific case when the two modalities \mathcal{M}_s and \mathcal{M}_d are the same and b) the *supervision transfer* happens at the very last prediction layer, instead of an arbitrary internal layer in representation Φ .

Our experiments in Section 4 demonstrate that this proposed method for transfer of supervision is a) effective at

learning good feature hierarchies, b) these hierarchies can be improved further with finetuning, and c) the resulting representation can be complementary to the representation in the source modality \mathcal{M}_s if the modalities permit.

4. Experiments

In this section we present experimental results for the NYUD2 dataset where we use color and depth images as the paired modalities, and on the JHMDB video dataset for which we use the RGB and optical flow frames as the two modalities.

Our general experimental framework consists of two steps. The first step is *supervision transfer* as proposed in Section 3, and the second step is to assess the quality of the transferred representation by using it for a downstream task. For both of the datasets we study, we consider the domain of RGB images as \mathcal{M}_s for which there is a large dataset of labeled images D_s in the form of ImageNet [6], and treat depth and optical flow respectively as \mathcal{M}_d . These choices for \mathcal{M}_s and \mathcal{M}_d are of particular practical significance, given the lack of large labeled datasets for depth images and optical flow, at the same time, the abundant availability of paired images coming from RGB-D sensors (for example Microsoft Kinect) and videos on the Internet respectively.

For our layered image representation models, we use convolutional neural networks (CNNs) [33, 31]. These networks have been shown to be very effective for a variety of image understanding tasks [7]. We experiment with the network architectures from Krizhevsky *et al.* [31] (denoted AlexNet), Simonyan and Zisserman [44] (denoted VGG), and use the models pre-trained on ImageNet [6] from the Caffe [28] Model Zoo.

We use an architecture similar to [31] for the layered representations for depth and flow images. We do this in order to be able to compare to past works which learn features on depth and flow images [17, 14]. Validating different CNN architectures for depth and flow images is a worthwhile scientific endeavor, which has not been undertaken so far, primarily because of lack of large scale labeled datasets for these modalities. Our work here provides a method to circumvent the need for a large labeled dataset for these and other image modalities, and will naturally enable exploring this question in the future, however we do not delve in this question in the current work.

We next describe our design choices for which layers to transfer supervision between, and the specification of the loss function f and the transformation function t . We experimented with what layer to use for transferring supervision, and found transfer at mid-level layers works best, and use the last convolutional layer pool5 for all experiments in the paper. Such a choice also resonates well with observations from [34] that lower layers in CNNs are modality

Does supervision transfer work?		How good is the transferred representation by itself?			Are the representations complementary?

Table 1: We evaluate different aspects of our *supervision transfer* scheme on the object detection task on the NYUD2 *val* set using the mAP metric. Left column demonstrates that our scheme for pre-training is better than alternatives like no pre-training, and copying over weights from RGB networks. The middle column demonstrates that our technique leads to transfer of mid-level semantic features which by themselves are highly discriminative, and that improving the quality of the supervisory network translated to improvements in the learned features. Finally, the right column demonstrates that the learned features on the depth images are still complementary to the features on the RGB image they were supervised with.

specific (and thus harder to transfer across modalities) and visualizations from [13] that neurons in mid-level layers are semantic and respond to parts of objects. Transferring at pool_5 also has the computational benefit that training can be efficiently done in a fully convolutional manner over the whole image.

For the function f , we use L_2 distance between the feature vectors, $f(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|_2^2$. We also tried $f(\mathbf{x}, \mathbf{y}) = \mathbf{1}(\mathbf{y} > \tau) \cdot \log p(\mathbf{x}) + \mathbf{1}(\mathbf{y} \leq \tau) \cdot \log(1 - p(\mathbf{x}))$ (where $p(x) = \frac{e^{\alpha x}}{1+e^{\alpha x}}$, $\mathbf{1}(x)$ is the indicator function), for some reasonable choices of α and τ but that resulted in worse performance in initial experiments and we did not experiment with it further.

Finally, the choice of the function t varies with different pairs of networks. As noted above, we train using a fully convolutional architecture. This requires the spatial resolution of the two layers i^* in Φ and L in Ψ to be similar, which is trivially true if the architectures Φ and Ψ are the same. When they are not (for example when we transfer from VGG net to AlexNet), we adjust the padding in the AlexNet to obtain the same spatial resolution at pool_5 layer.

This apart, we introduce an adaptation layer comprising of 1×1 convolutions followed by *ReLU* to map from the representation at layer L in Ψ to layer i^* in Φ . This accounts for difference in the number of neurons (for example when adapting from VGG to AlexNet), or even when the number of neurons are the same, allows for domain specific fitting. For VGG to AlexNet transfer we also needed to introduce a scaling layer to make the average norm of features comparable between the two networks.

4.1. Transfer to Depth Images

We first demonstrate how we transfer supervision from color images to depth images as obtained from a range sensor like the Microsoft Kinect. As described above, we do this set of experiments on the NYUD2 dataset [41] and show results on the task of object detection and instance segmen-

tation [17]. The NYUD2 dataset consists of 1449 paired RGB and D images. These images come from 464 different scenes and were hand selected from the full video sequence while ensuring ensure diverse scene content [41]. The full video sequence that comes with the dataset has over 400K RGB-D frames, we use 10K of these frame pairs for supervision transfer.

In all our experiments we report numbers on the standard *val* and *test* splits that come with the dataset [41, 17]. Images in these splits have been selected while ensuring that all frames belonging to the same scene are contained entirely in exactly one split. We additionally made sure only frames from the corresponding training split were used for supervision transfer.

The downstream task that we study here is that of object detection. We follow the experimental setup from Gupta *et al.* [17] for object detection and study the 19 category object detection problem, and use mean average precision (mAP) to measure performance.

Baseline Detection Model We use the model from Gupta *et al.* [17] for object detection. Their method builds off R-CNN [13]. In our initial experiments we adapted their model to the more recent Fast R-CNN framework [12]. We summarize our key findings here. First, [17] trained the final detector on both RGB and D features jointly. We found training independent models all the way and then simply averaging the class scores before the SoftMax performed better. While this is counter-intuitive, we feel it is plausible given limited amount of training data. Second, [17] use features from the $f_{\text{C}6}$ layer and observed worse performance when using $f_{\text{C}7}$ representation; in our framework where we are training completely independent detectors for the two modalities, using $f_{\text{C}7}$ representation is better than using $f_{\text{C}6}$ representation. Finally, using bounding box regression boosts performance. Here we simply average the predicted regression target from the detectors on the two modalities. All this analysis helped us boost the mean AP on the *test*

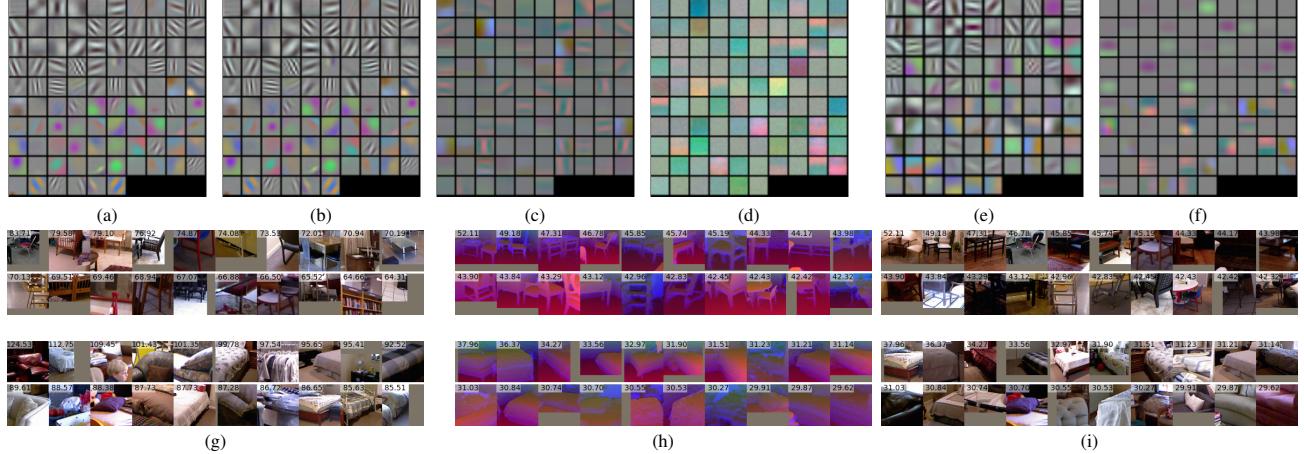

Figure 2: Visualization of learned filters (best viewed in color): (a) visualizes filters learned on RGB images from ImageNet data by AlexNet. (b) shows these filters after the finetuning on HHA images, and hardly anything changes visually. (c) shows HHA image filters from our pre-training scheme, which are much different from ones that are learned on RGB images. (d) shows HHA image filters learned without any pre-training. (e) shows optical flow filters learned by [14]. Note that they initialize these filters from RGB filters and these also do not change much over their initial RGB filters. (f) shows filters we learn on optical flow images, which are again very different from filters learned on RGB or HHA images. (g) shows image patches corresponding to highest scoring activations for two neurons in the RGB CNN. (h) shows HHA image patches corresponding to highest scoring activations of the same neuron in the supervision transfer depth CNN. (i) shows the corresponding RGB image patch for these depth image patches for ease of visualization.

set from 38.80% as reported by [17, 16] to 44.39%, using the same CNN network and supervision. This already is the state-of-the-art result on this dataset and we use this as a baseline for the rest of our experiments. We denote this model as ‘[17] + Fast R-CNN’. We followed the default setup for training Fast R-CNN, 40K iterations, base learning rate of 0.001 and stepping it down by a factor of 10 after every 30K iterations, except that we finetune all the layers, and use 688px length for the shorter image side. We used RGB-D box proposals from [17] for all experiments.

Note that Gupta *et al.* [17] embed depth images into a geocentric embedding which they call HHA (HHA encodes horizontal disparity, height above ground and angle with gravity) and use the AlexNet architecture to learn HHA features and *copy over the weights from the RGB CNN that was trained for 1000 way classification* [31] on ImageNet [6] to initialize this network. All through this paper, we stick with using HHA embedding¹ to represent the input depth images, and their network architecture, and show how our proposed *supervision transfer* scheme improves performances over their technique for initialization. We summarize our various transfer experiments below:

Does supervision transfer work? The first question we investigate is if we are able to transfer supervision to a new modality. To understand this we conducted the following three experiments:

1. no init (1A): randomly initialize the depth network using weight distributions typically used for training on ImageNet and simply train this network for the final task. While

training this network we train for 100K iterations, start with a learning rate on 0.01 and step it down by a factor of 10 every 30K iterations.

2. copy from RGB (1B): copy weights from a RGB network that was trained on ImageNet. This is same as the scheme proposed in [17]. This network is then trained using the standard Fast R-CNN settings.

3. supervision transfer (1C): train layers conv1 through pool5 from random initialization using the *supervision transfer* scheme as proposed in Section 3, on the 5K paired RGB and D images from the video sequence from NYUD2 for scenes contained in the training set. We then plug in these trained layers along with randomly initialized fc6, fc7 and classifier layers for training with Fast R-CNN. We report the results in Table 1. We see that ‘copy from RGB’ surprisingly does better than ‘no init’, which is consistent with what Gupta *et al.* report in [17], but our scheme for *supervision transfer* outperforms both these baselines by a large margin pushing up mean AP from 25.1% to 29.7%. We also experimented with using a RGB network Ψ that has been adapted for object detection on this dataset for supervising the transfer (1D) and found that this boosted performance further from 29.7% to 30.5% (1D in Table 1, AlexNet* indicates RGB AlexNet that has been adapted for detection on the dataset). We use this scheme for all subsequent experiments.

Visualizations. We visualize the filters from the first layer for these different schemes of transfer in Figure 2(a-f), and observe that our training scheme learns reasonable filters and find that these filters are of different nature than fil-

¹We use the term depth and HHA interchangeably.

val set: Performance on NYUD2 *val* set where we observe similar boosts in performance when using hyper-column transform with our learned feature hierarchies (learned using supervision transfer on depth images) as obtained with more standard feature hierarchies learned on ImageNet on RGB images.

ters learned on RGB images. In contrast, note that schemes which initialize depth CNNs with RGB CNNs weights, filters in the first layer change very little. We also visualize patches giving high activations for neurons paired across RGB and D images Figure 2(g-i). High scoring patches from RGB CNN (AlexNet in this case), correspond to parts of object (g), high scoring patches from the depth CNN also corresponds to parts of the same object class (h and i).

How good is the transferred representation by itself?

The next question we ask is if our *supervision transfer* scheme transfers good representations or does it only provide a good initialization for feature learning. To answer this question, we conducted the following experiments:

1. Quality of transferred pool5 representation (2A, 2B): The first experiment was to evaluate the quality of the transferred pool5 representation. To do this, we froze the network parameters for layers conv1 through pool5 to be those learned during the transfer process, and only learn parameters in fc6, fc7 and classifier layers during Fast R-CNN training (2B ‘supervision transfer adapted (ft fc only)'). We see that there is only a moderate degradation in performance for our learned features from 30.5% (1D) to 30.0% (2B) indicating that the features learned on depth images at pool5 are discriminative by themselves. In contrast, when freezing weights when copying from ImageNet (2A), performance degrades significantly to 19.8%.

2. Improved transfer using better supervising network Φ (2C, 2D): The second experiment investigated if performance improves as we improve the quality of the supervising network. To do this, we transferred supervision from VGG net instead of AlexNet (2C)². VGG net has been shown to be better than AlexNet for a variety of vision tasks. As before we report performance when freezing parameters till pool5 (2C), and learning all the way (2D). We see that using a better supervising net results in learning better features for depth images: when the representation is frozen till pool5 we see performance improves from 30.0% to 32.2%, and when we finetune all the layers performance goes up to 33.6% as compared to 30.5% for AlexNet.

²To transfer from VGG to AlexNet, we use 150K transfer iterations instead of 100K. Running longer helps for VGG to AlexNet transfer by 1.5% and much less (about 0.5%) for AlexNet to AlexNet transfer.

test	modality	RGB Arch.	D Arch.	AP^r at 0.5	AP^r at 0.7
[20]	RGB	AlexNet	-	23.4	13.4
Gupta <i>et al.</i> [16]	RGB + D	AlexNet	AlexNet	37.5	21.8
Our (<i>supervision transfer</i>)	RGB + D	AlexNet	AlexNet	40.5	25.4
[20]	RGB	VGG	-	31.0	17.7
Our (<i>supervision transfer</i>)	RGB + D	VGG	AlexNet	42.1	26.9

Table 3: Region detection average precision AP^r on NYUD2 test set.

Is the learned representation complementary to the representation on the source modality? The next question we ask is if the representation learned on the depth images complementary to the representation on the RGB images from which it was learned. To answer this question we look at the performance when using both the modalities together. We do this the same way that we describe for the baseline model and simply average the category scores and regression targets from the RGB and D detectors. Table 1(right) reports our findings. Just using RGB images (3A) gives us a performance of 22.3%. Combining this with the HHA network as initialized using the scheme from Gupta *et al.* [17] (3B) boosts performance to 33.8%. Initializing the HHA network using our proposed supervision transfer scheme when transferring from AlexNet* to AlexNet (3C) gives us 35.6% and when transferring from VGG* to AlexNet (3D) gives us 37.0%. These results show that the representations are still complementary and using the two together can help the final performance.

Does supervision transfer lead to meaningful intermediate layer representations? The next questions we investigate is if the intermediate layers learned in the target domain M_d through *supervision transfer* carry useful information. [30] hypothesize that information from intermediate layers in such hierarchies carry information which may be useful for fine grained tasks. Jones and Malik [29] and Weber and Malik [51] and in more recent work Hariharan *et al.* [20] and Long *et al.* [36] operationalize this and demonstrate improvements for fine grained tasks like correspondence estimation and segmentation. Here we investigate if the representations learned using *supervision transfer* also share this property. To test this, we follow the hyper-column architecture from Hariharan *et al.* [20] and study the task of simultaneous detection and segmentation (SDS) [19] and investigate if the use of hyper-columns with our trained networks results in similar improvements as obtained when using more traditionally trained CNNs. We report the results in Table 2. On the NYUD2 dataset, the hyper-column transform improves AP^r from 26.3% to 29.8% when using AlexNet for RGB images. We follow the same experimental setup as proposed in [18], and fix the CNN parameters (to a network that was finetuned for detection on NYUD2 dataset) and only learn the classifier parameters and use features from pool2 and conv4 layers in addition to fc7 for

pool1	pool2	conv3	conv4	pool5	fc6	fc7	conv3 + fc7
24.4	28.4	30.6	29.9	30.5	29.7	27.7	31.3

Table 4: Mean AP on NYUD2 *val* set as a function of layer used for supervision transfer.

figure ground prediction. When doing the same for our *supervision transfer* network we observe a similar boost in performance from 28.4% to 31.5% when using the hyper-column transform. This indicates that models trained using *supervision transfer* not only learn good representations at the point of supervision transfer (`pool5` in this case), but also in the intermediate layers of the network.

How does performance vary as the transfer point is changed? We now study how performance varies as we vary the layer used for supervision transfer. We stick to the same experimental setup as used for Exp. 1D in Table 1, and conduct supervision transfer at different layers of the network. Layers above the transfer point are initialized randomly and learned during detector training. For transferring features from layers 1 to 5, we use fully convolutional training as before. But when transferring `fc6` and `fc7` features we compute them over bounding box proposals (we use RGB-D MCG bounding box proposals [17]) using Spatial Pyramid Pooling on `conv5` [21, 12].

We report the obtained AP on the NYUD2 *val* set in Table 4. We see performance is poor when transferring at lower layers (`pool1` and `pool2`). Transfer at layers `conv3`, `conv4`, `pool5` works comparably, but performance deteriorates when moving to further higher layers (`fc6` and `fc7`). This validates our choice for using an intermediate layer as a transfer point. We believe the drop in performance at higher layers is an artifact of the amount of data used for supervision transfer. With a richer and more diverse dataset of paired images we expect transfer at higher layers to work similar or better than transfer at mid-layers.

We also conducted some initial experiments with using multiple transfer points. When transferring at `conv3` and `fc7` we observe performance improves over transferring at either layer alone, indicating learning is facilitated when supervision is closer to parameters being learned. We defer exploration of other choices in this space for future work.

Is input representation in the form of HHA images still important? Given our tool for training CNNs on depth images, we can now investigate the question whether hand engineering the input representation is still important. We conduct an experiment in exactly the same settings as Exp. 1D except that we work with disparity images (replicated to have 3 channels) instead of HHA images. This gives a mAP of 29.2% as compared to 30.5% for the HHA images. The difference in performance is smaller than what [17] reports but still exists, which suggests that encoding information into geocentric channels through the HHA embedding is still useful [17].

	Train on MS COCO and adapt to NYUD2 using supervision transfer							Train on NYUD2	
	bed	chair	sink	sofa	table	tv	toilet	mean	mean
RGB	51.6	26.6	25.1	43.1	14.4	12.9	57.5	33.0	35.7
D	59.4	27.1	23.8	32.2	13.0	13.6	43.8	30.4	45.0
RGB + D	60.2	35.3	27.5	48.2	16.5	17.1	58.1	37.6	54.4

Table 5: Adapting RGB object detectors to RGB-D images: We transfer object detectors trained on RGB images (on MS COCO dataset) to RGB-D images in the NYUD2 dataset, without using any annotations on depth images. We do this by learning a model on depth images using supervision transfer and then use the RGB object detector trained on the representation learned on depth images. We report detection AP(%) on NYUD2 *test* set. These transferred detectors work well on depth images even without using any annotations on depth images. Combining predictions from the RGB and depth image improves performance further.

Applications to zero-shot detection on depth images. *Supervision transfer* can be used to transfer detectors trained on RGB images to depth images. We do this by the following steps. We first train detectors on RGB images. We then split the network into two parts at an appropriate mid-level point to obtain two networks Γ_{rgb}^{lower} and Γ_{rgb}^{upper} . We then use the lower domain specific part of the network Γ_{rgb}^{lower} to train a network Γ_d^{lower} on depth images to generate the same representation as the RGB network Γ_{rgb}^{lower} . This is done using the same supervision transfer procedure as before on a set of unlabeled paired RGB-D images. We then construct a ‘franken’ network with the lower domain specific part coming from Γ_d^{lower} and the upper more semantic network coming from Γ_{rgb}^{upper} . We then simply use the output of this franken network on depth images to obtain zero-shot object detection output.

More specifically, we use Fast R-CNN with AlexNet CNN to train object detectors on the MS COCO dataset [35]. We then split the network right after the convolutional layers `pool5`, and train a network on depth images to predict the same `pool5` features as this network on unlabeled RGB-D images from the NYUD2 dataset (using frames from the *trainval* video sequences). We study all 7 object categories that are shared between MS COCO and NYUD2 datasets, and report the performance in Table 5. We observe our zero-shot scheme for transferring detectors across modalities works rather well, and results in good performance. While the RGB detector trained on MS COCO obtains a mean AP of 33.0% on these categories, our zero-shot detector on D images performs comparably and has a mean AP of 30.4%. Note that in doing so we have not used any annotations from the NYUD2 dataset (RGB or D images). Furthermore, combining predictions from RGB and D object detectors results in boost over just using the detector on the RGB image giving a performance of 37.6%. Performance when training detectors using annotations from the NYUD2 dataset (last column in Table 5) is obviously much higher.

Performance on test set. Finally, we report the perfor-

method	modality	RGB Arch.	D Arch.	mean
Fast R-CNN [12]	RGB	AlexNet	-	27.8
Fast R-CNN [12]	RGB	VGG	-	38.8
Gupta <i>et al.</i> [17]	RGB + D	AlexNet	AlexNet	38.8
Gupta <i>et al.</i> [16]	RGB + D	AlexNet	AlexNet	41.2
Gupta <i>et al.</i> [17] + Fast R-CNN	RGB + D	AlexNet	AlexNet	44.4
Our (<i>supervision transfer</i>)	RGB + D	AlexNet	AlexNet	47.1
Gupta <i>et al.</i> [17] + Fast R-CNN	RGB + D	VGG	AlexNet	46.2
Our (<i>supervision transfer</i>)	RGB + D	VGG	AlexNet	49.1
Gupta <i>et al.</i> [17] + Fast R-CNN	D	-	AlexNet	34.2
Our (<i>supervision transfer</i>)	D	-	AlexNet	41.7

Table 6: Object detection mean AP(%) on NYUD2 test set: We compare our performance against several state-of-the-art methods. RGB Arch. and D Arch. refers to the CNN architecture used by the detector. We see when using just the depth image, our method is able to improve performance from 34.2% to 41.7%. When used in addition to features from the RGB image, our learned features improve performance from 44.4% to 47.1% (when using AlexNet RGB features) and from 46.2% to 49.1% (when using VGG RGB features) over past methods for learning features from depth images. We see improvements across almost all categories, performance on individual categories is tabulated in supplementary material.

mance of our best performing supervision transfer scheme (VGG * → AlexNet) on the *test* set in Table 6. When used with AlexNet for obtaining color features, we obtain a final performance of 47.1% which is about 2.7% higher than the current state-of-the-art on this task (Gupta *et al.* [17] Fast R-CNN). We see similar improvements when using VGG for obtaining color features (46.2% to 49.1%). The improvement when using just the depth image is much larger, 41.7% for our final model as compared to 34.2% for the baseline model which amounts to a 22% relative improvement. Note that in obtaining these performance improvements we are using exactly the same CNN architecture and amount of labeled data. We also report performance on the SDS task in Table 3 and obtain state-of-the-art performance of 40.5% as compared to previous best 37.5% [16] when using AlexNet, using VGG CNN for the RGB image improves performance further to 42.1%.

Training Time. Finally, we report the amount of time it takes to learn a model using supervision transfer. For AlexNet to AlexNet supervision transfer we trained for 100K iterations which took a total of 2.5 hours on a NVIDIA k40 GPU. This is a many orders of magnitude faster than training models from random initialization on ImageNet scale data using class labels.

4.2. Transfer to Flow Images

We now report our experiments for transferring supervision to optical flow images. We consider the end task of

	RGB		optical flow			Our Sup Transfer
	[14]	[14] + [12]	[14] Sup PreTr	[14] + [12] Sup PreTr	Random Init	
mean AP	27.0	32.0	24.3	38.4	31.7	35.7

Table 7: Action Detection AP(%) on the JHMDB test set: We report action detection performance on the *test* set of JHMDB using RGB or flow images. Right part of the table compares our method *supervision transfer* against the baseline of random initialization, and the ceiling using fully supervised pre-training method from [14]. Our method reaches more than half the way towards fully supervised pre-training.

action detection on the JHMDB dataset. The task is to detect people doing actions like *catch*, *clap*, *pick*, *run*, *sit* in frames of a video. Performance is measured in terms of mean average precision as in the standard PASCAL VOC object detection task and what we used for the NYUD2 experiments in Section 4.1.

A popular technique for getting better performance at such tasks on video data is to additionally use features computed on the optical flow between the current frame and the next frame [43, 14], and we use our *supervision transfer* scheme to learn features for optical flow images in this context.

Detection model For JHMDB we use the experimental setup from Gkioxari and Malik [14] and study the 21 class task. Here again, Gkioxari and Malik build off of R-CNN and we first adapt their system to use Fast R-CNN, and observe similar boosts in performance as for NYUD2 when going from R-CNN to Fast R-CNN framework (Table 7, full table with per class performance is in the supplementary material). We denote this model as [14]+[12]. We attribute this large difference in performance to a) bounding box regression and b) number of iterations used for training.

Supervision transfer performance We use the videos from UCF 101 dataset [47] for our pre-training. Note that we do not use any labels provided with the UCF 101 dataset, and simply use the videos as a source of paired RGB and flow images. We take 5 frames from each of the 9K videos in the *train1* set. We report performance on JHMDB *test* set in Table 7. Note that JHMDB has 3 splits and as in past work, we report the AP averaged across these 3 splits.

We report performance for three different schemes for initializing the flow model: a) **Random Init** (No PreTr) when the flow network is initialized randomly using the weight initialization scheme used for training a RGB model on ImageNet, b) **Supervised Pre-training** ([14]+[12] Sup PreTr) on flow images from UCF 101 for the task of video classification starting from RGB weights as done by Gkioxari and Malik [14] and c) **supervision transfer** (Our Sup Transfer) from an RGB model to train optical flow model as per our proposed method. We see that our scheme for *supervision transfer* improves performance from 31.7% achieved when using random initialization to 35.7%, which

is more than half way towards what fully supervised pre-training can achieve (38.4%), thereby illustrating the efficacy of our adaptation scheme.

Conclusion We have presented an algorithm for transfer of learned representations from a well labeled modality to new unlabeled modalities using unlabeled paired images from the two modalities. This enables us to learn rich representations on unlabeled modalities and obtain large boosts in performance. We believe the advances presented in this paper will allow us to effectively use new modalities for obtaining better performance on standard vision tasks. Code, data and pretrained models are available at <https://github.com/s-gupta/fast-rcnn/tree/distillation>.

Acknowledgments: The authors would like to thank Georgia Gkioxari for sharing her wisdom and experimental setup for the UCF 101 and JHMDB datasets. This work was supported by ONR SMARTS MURI N00014-09-1-1051, a Berkeley Graduate Fellowship, a Google Fellowship in Computer Vision and a NSF Graduate Research Fellowship. We gratefully acknowledge NVIDIA corporation for the donation of Tesla and Titan GPUs used for this research.

A. Supplementary Material

1. **Per category average precision:** We report per category numbers for summary tables on *test* sets in the main paper.
2. **Sample Detection and SDS output:** We show sample detections and SDS output for the categories we study. We sample 18 detections uniformly from the top k ($= 0.75 \times$ number of instances) detections for each category: bed (Figure 3), chair (Figure 4), sofa (Figure 5), toilet (Figure 6), table (Figure 7).

B. Document Changelog

v1 Initial version

v2 Major changes: additional discussion of multi-modal literature, visualization of neural activations in Figure 2(g-i), additional experiments about quality of intermediate layers, performance as a function of transfer point, utility of HHA embedding over disparity images, zero-shot detection on depth images. Minor edits all over the text.

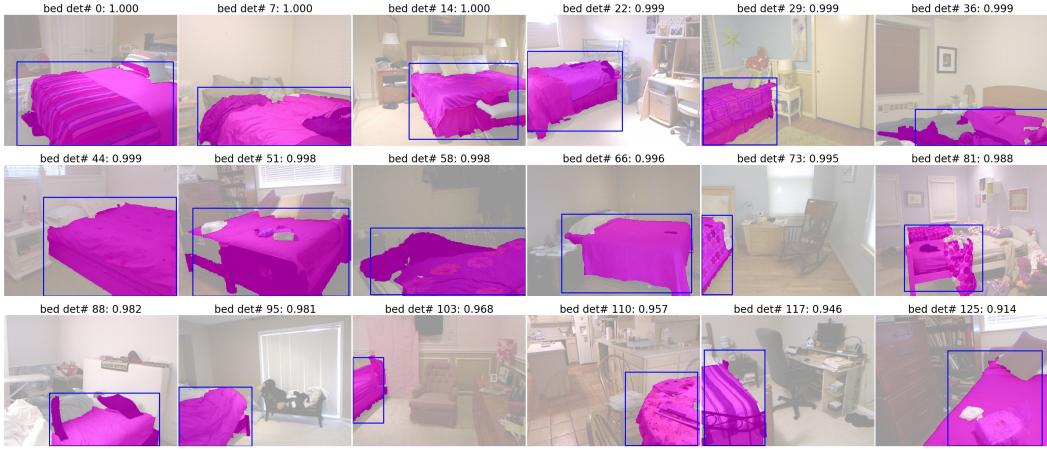

Figure 3: Sample detections and segmentation masks for bed on NYUD2 *test* set.

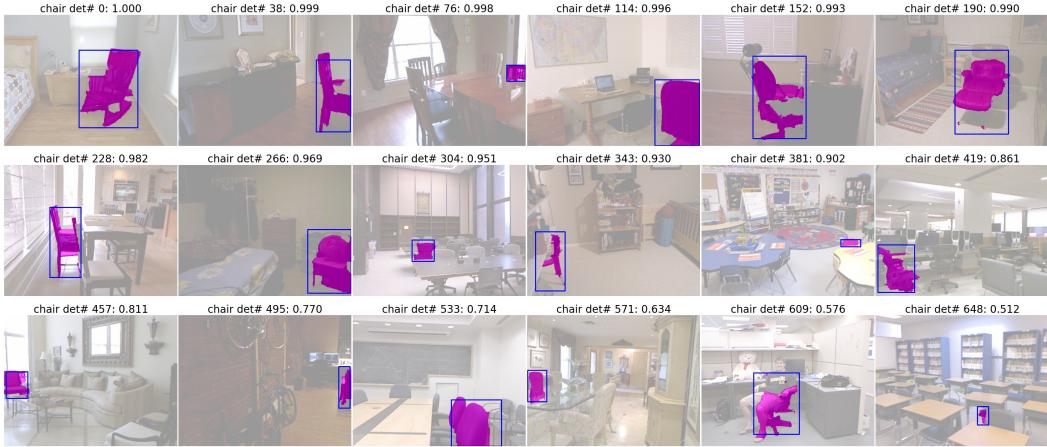

Figure 4: Sample detections and segmentation masks for chair on NYUD2 *test* set.

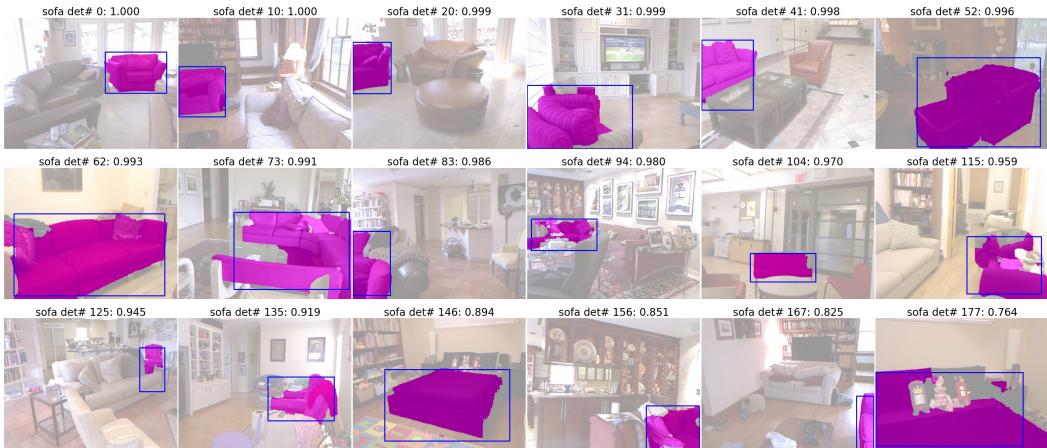

Figure 5: Sample detections and segmentation masks for sofa on NYUD2 *test* set.

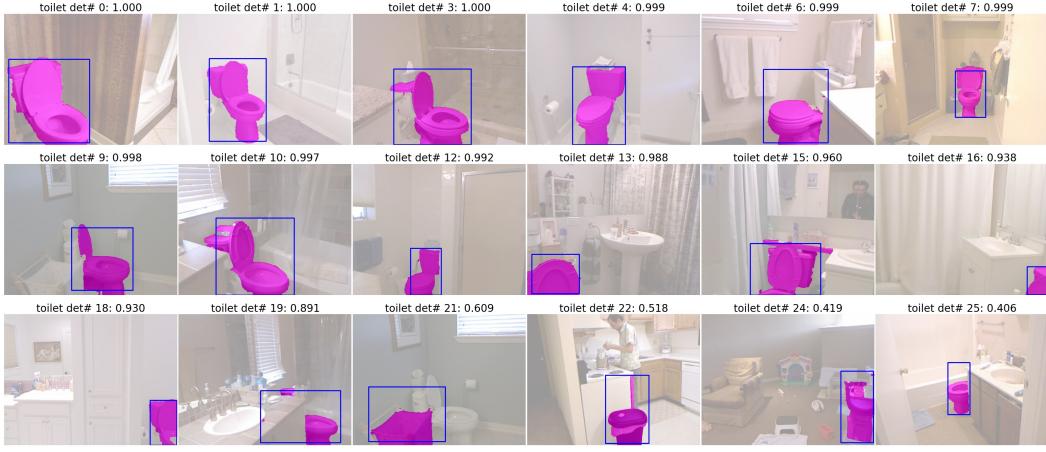

Figure 6: Sample detections and segmentation masks for toilet on NYUD2 *test* set.

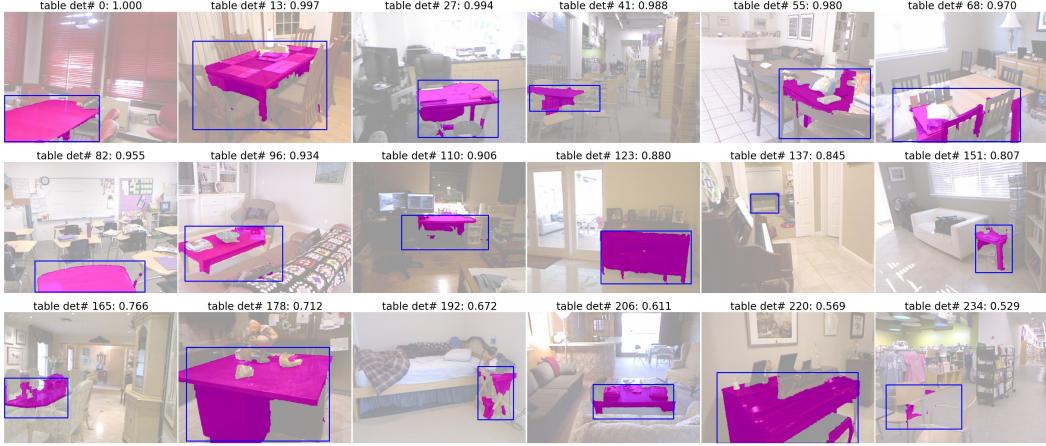

Figure 7: Sample detections and segmentation masks for table on NYUD2 *test* set.

Table 9: Object Detection AP(%) on NYUD2 test set: We compare our performance against several state-of-the-art methods. RGB Arch. and D Arch. refers to the CNN architecture used by the detector. We see when using just the depth image, our method is able to improve performance from 34.2% to 41.7%. When used in addition to features from the RGB image, our learned features improve performance from 44.4% to 47.1% (when using AlexNet RGB features) and from 46.2% to 49.1% (when using VGG RGB features) over past methods for learning features from depth images. Analogous to summary Table 6 in the main paper.

method	Supervision	modality	brush hair	catch	clap	climb stairs	golf	jump	kick ball	pick	pour	pullup	push	run	shoot ball	shoot bow	shoot gun	sit	stand	swing baseball	throw	walk	wave	mean

Table 10: Action Detection AP(%) on the JHMDB test set: We report action detection performance on the *test* set of JHMDB using RGB or flow images. Bottom part of the table, compares our method *supervision transfer* against the baseline of random initialization, and the ceiling using fully supervised pre-training method from [14]. Our method reaches more than half the way towards fully supervised pre-training. Analogous to Table 7 in the main paper.
